Abstract

We synthesized a quasi-two-dimensional distorted triangular lattice antiferromagnet $\text{Ca}_3\text{CoNb}_2\text{O}_9$, in which the effective spin of Co^{2+} is $1/2$ at low temperatures, whose magnetic properties were studied by dc susceptibility and magnetization techniques. The x-ray diffraction confirms the quality of our powder samples. The large Weiss constant $\theta_{CW} \sim -55$ K and the low Neel temperature ($T_N \sim 1.45$ K) give a frustration factor $f (=|\theta_{CW}/T_N|) \approx 38$, suggesting that $\text{Ca}_3\text{CoNb}_2\text{O}_9$ resides in strong frustration regime. Slightly below T_N , deviation between the susceptibility data under zero-field cooling (ZFC) and field cooling (FC) is observed. A new magnetic state with $1/3$ of the saturate magnetization M_s is suggested in the magnetization curve at 0.46 K. Our study indicates that $\text{Ca}_3\text{CoNb}_2\text{O}_9$ is an interesting material to investigate magnetism in triangular lattice antiferromagnets with weak anisotropy.

I. INTRODUCTION

Geometrically frustrated classical/quantum magnets, in which the simultaneous minimization of local interaction energies cannot compromise with lattice geometry, have attracted a lot research interest in condensed matter physics due to their novel magnetic orders and exotic excitations¹⁻³. The two dimension (2D) triangular-lattice Heisenberg antiferromagnet (TLHAF) is a paradigmatic example of frustrated magnet. Theoretical studies have reached a consensus that the ground state of the regular TLHAF with $S=1/2$ selects the 120° non-collinear structure in the absence of field, which is similar to classical Heisenberg model⁴⁻⁶. While under external field, the quantum fluctuations can stabilize a novel up-up-down quantum state, with a corresponding $1/3$ plateau in the magnetization process⁷⁻¹¹. This model has given an excellent description on the magnetism of compounds such as $\text{Ba}_3\text{CoSb}_2\text{O}_9$ ¹², $\text{Ba}_3\text{NiNb}_2\text{O}_9$ ¹³ and $\text{Ba}_3\text{CoNb}_2\text{O}_9$ ¹⁴.

For the TLHAF with spatially anisotropic exchange, for example Cs_2CuBr_4 , in addition to the up-up-down phase, many other phases with $\frac{1}{2}, \frac{5}{9}, \frac{2}{3}$ of M_s were observed in the magnetization curve¹⁵. Theoretical studies suggested that the interplay of spatially anisotropic interactions and quantum fluctuations should play an important role in new phases of Cs_2CuBr_4 ^{11,15,16}. Therefore, it's of great interest to explore novel magnetic states in distorted triangular lattice antiferromagnets (DTLAF).

Recently, a new DTLAF material $\text{Ca}_3\text{CoNb}_2\text{O}_9$ was reported, whose structure was determined by neutron powder diffraction¹⁷, but its magnetism has not been studied yet. As shown in Fig. 1 (a), $\text{Ca}_3\text{CoNb}_2\text{O}_9$ crystallizes in monoclinic structure (space group $P2_1/c$). There are two inequivalent Co^{2+} ions coordinated in two kinds of twisted CoO_6 octahedra which are shown by an enlarged view [see Fig. 1 b]. The Co^{2+} ions form almost perfect equilateral-triangular lattice layers parallel to the ab plane and are separated by two non-magnetic NbO_6 octahedra and Ca^{2+} ions. The distance between $\text{Co}(1)$ - $\text{Co}(1)$, $\text{Co}(1)$ - $\text{Co}(2)$, $\text{Co}(2)$ - $\text{Co}(2)$ are 0.5462 \AA , 0.5521 \AA and 0.5462 \AA , respectively. Considering the nonuniformity of Co^{2+} sites, there should be three different dominant exchange interactions between nearest neighboring Co^{2+} ions for $\text{Ca}_3\text{CoNb}_2\text{O}_9$, which are labeled as J_1 , J_2 and J_3 respectively [Fig. 1 (c)], the values of them need to be determined by future work. Meanwhile, due to the loss of an inversion center between $\text{Co}(1)$ and $\text{Co}(2)$, Dzyaloshinsky-Moriya (DM) interactions should also present in $\text{Ca}_3\text{CoNb}_2\text{O}_9$. Therefore, this represents a prototype

FIG. 1: (color online) (a) A schematic crystal structure for $\text{Ca}_3\text{CoNb}_2\text{O}_9$. (b) Two inequivalent Co sites, Co(1) coordinated in blue octahedra environment and Co(2) located in red octahedra, forming the magnetic layers. Local parameters of Co(1)O₆ and Co(2)O₆ octahedra are also presented in an expanded view. (c) The triangular lattice of Co²⁺ parallel to the ab plane. Three exchange interactions are illustrated: J_1 , J_2 and J_3 .

TAFM system with spatial anisotropy and DM interactions. In this work, we report our magnetization studies on $\text{Ca}_3\text{CoNb}_2\text{O}_9$. We find strong frustration and the existence of long-range order antiferromagnetism(LROAFM) at very low temperatures in this system.

II. MATERIALS AND METHODS

We synthesized polycrystalline samples of $\text{Ca}_3\text{CoNb}_2\text{O}_9$ by a standard solid state reaction method. CaCO_3 (5N Alfa), CoO (>3N Alfa) and Nb_2O_5 (4N Alfa) powders with stoichiometric ratio were ground sufficiently and pressed into pellets. After sintering in air at 850 °C for 10 hours, the pellets were then calcined at 1200 °C for 72 hours with intermediate grinding and re-pelleting. The room temperature powder X-ray diffraction measurement was performed on a Bruker XRD diffractometer with $\text{CuK}\alpha$ radiation. The susceptibility measurements in the temperature range 2 K - 300 K were performed with vibrating sample magnetometer (VSM) loaded on a physical property measurement system (Quantum Design PPMS). Magnetic measurements below 2 K were performed using a magnetic property

The green solid line is the calculated XRD pattern for powder $\text{Ca}_3\text{CoNb}_2\text{O}_9$. The vertical lines indicate the reflection positions for $\text{Ca}_3\text{CoNb}_2\text{O}_9$. The difference curve is also presented as the black solid line.

measurement system (Quantum Design MPMS) with a ^3He insert at McMaster University.

III. RESULTS

The XRD patterns of polycrystalline $\text{Ca}_3\text{CoNb}_2\text{O}_9$ samples are presented in Fig. 2. Refinement of the observed diffraction peaks using the structure parameters obtained from previous neutron diffraction¹⁷ gives a final weighted residual error $R_{wp} = 2.64$, which means that our XRD data match well with the calculated results. The obtained structure parameters $a = 9.5988(9) \text{ \AA}$, $b = 5.4576(3) \text{ \AA}$ and $c = 16.8643(9) \text{ \AA}$ are also consistent with previous results¹⁷. No additional impurity peak is found in the whole diffraction range from 5° to 120° indicating that there is no obvious impurity phase in our samples.

The dc susceptibility and its inverse above 2 K under a field of 0.1 T for $\text{Ca}_3\text{CoNb}_2\text{O}_9$ are shown in Fig. 3. The $1/\chi$ deviates from the Curie-Weiss curve at around 50 K, which is because of the frustration when $T < \theta_{CW}$. The susceptibility data above 100 K can be fit by the Curie-Weiss formula: $\chi_M = C/(T - \theta_{CW}) + \chi_0$, where C is the Curie constant, θ_{CW} is the Weiss constant, and the χ_0 is the temperature-independent paramagnetic susceptibility.

FIG. 3: (color online) The dc susceptibility ($\chi = M/H$) and its inverse measured at 0.1 T. The solid line is a linear Curie-Weiss fitting of χ in temperature range 100 -300 K.

The fitting gives an effective moment of $5.1 \mu_B$ and a Weiss constant of $\theta_{CW} \sim -55$ K. Considering the contribution from the orbital angular momentum, the value of the moment is reasonable for the Co^{2+} ion in the high-spin state¹⁸. The negative Weiss constant reflects dominant antiferromagnetic interactions between Co^{2+} ions. The large Weiss temperature and the absence of magnetic ordering down to 2 K imply the presence of strong frustration in this system.

To study the ground state magnetism of $\text{Ca}_3\text{CoNb}_2\text{O}_9$, we performed susceptibility measurements down to 0.46 K with ZFC and FC methods. As shown in Fig. 4 (a), under a 0.01 T external field, both ZFC and FC susceptibility increase with cooling. With further cooling, a cusp occurs at around 1.45 K, which indicates a transition from the paramagnetic phase to an ordered state. The susceptibility is less than 0.2 emu/mol Co^{2+} in the ordered state, which suggests a long-range order antiferromagnetism (LROAFM). Combined with the large Weiss constant obtained above, the frustration factor $f(=|\theta_{CW}|/T_N)$ is about 38, which is comparable to that of strong frustrated regular TLHAF $\text{Ba}_3\text{CoNb}_2\text{O}_9$ ($\theta_{CW} = -51$ K and $T_{N1} = 1.36$ K)¹⁴. In contrast to the regular triangular lattice antiferromagnet $\text{Ba}_3\text{CoNb}_2\text{O}_9$, $\text{Ca}_3\text{CoNb}_2\text{O}_9$ has DM interactions and spatially anisotropic exchange interactions. Theoretical studies suggested that both interactions release frustration and enhance the LROAFM in general^{19,20}. For $\text{Ca}_3\text{CoNb}_2\text{O}_9$, however, the anisotropy does not lift up

FIG. 4: (color online) (a)-(f) dc susceptibility down to 0.46 K after ZFC and FC measured at 0.01 T, 0.1 T, 0.2 T, 0.5 T, 0.65 T and 1 T respectively.

magnetic ordering temperature significantly, which suggests that the DM interactions and spatial anisotropy are weak.

The magnetically ordered ground states were expected for the insulating triangular lattice antiferromagnets, including isotropic Heisenberg¹⁴, XXZ^[21] and distorted¹¹ models. Experimentally, almost all triangular antiferromagnets have been found with LROAFM at low temperatures, except κ -(BEDT-TTF)₂Cu₂(CN)₃, which is probably closer to a Hubbard model²¹. Therefore, the LROAFM state is natural for our triangular lattice antiferromagnet.

At $T \sim 1.2$ K, which is slightly below T_N , deviation appears between the ZFC and FC data under 0.01 Tesla field [Fig. 4. (a)]. We further measure dc susceptibility after FC and ZFC at higher fields[see Fig. 4 (b)-(f)]. Under a 0.1 Tesla field, the FC susceptibility is suppressed slightly below T_N , while the suppression effect is much stronger for the ZFC data, resulting in an enhancement of the deviation between the FC and ZFC data. With further increasing fields, the discrepancy is gradually suppressed monotonously and completely removed by a field of 1 T, while the position of T_N remains at 1.45 K.

The deviation between ZFC and FC susceptibility data at low measurement fields

was reported in some spin-canted antiferromagnets. For example, in DTLAFM $\text{Cu}_2(\text{OH})_3(\text{C}_m\text{H}_{2m+1}\text{COO})$, $m = 7, 9, 11$ ²² the DM interactions were suggested to play an essential role to the spin canting. A similar situation may occur in $\text{Ca}_3\text{CoNb}_2\text{O}_9$, where the DM interactions assist the canting of antiferromagnetic moments.

The bifurcation of ZFC and FC susceptibility was also seen in spin glass system with spin-freezing. Earlier theoretical studies suggested that the spin glass phase usually occurs in frustrated systems with quenched disorder^{23,24}. However, spin glass can also be realized in system with competing ferro-and antiferromagnetic bonds distributed in a certain rule, rather than a random way²⁵. Experimentally, the spin freezing transition has been found recently in several nominally disorder-free frustrated systems such as $\text{Y}_2\text{Mo}_2\text{O}_7$ ^{26,27}, $\text{Gd}_3\text{Ga}_5\text{O}_{12}$ ²⁸, ZnCr_2O_4 ²⁹, CsVCl_3 ³⁰, $\text{Cu}_2(\text{OH})_3(\text{C}_m\text{H}_{2m+1}\text{COO})$, $m = 7, 9, 11$ ²². The spin glass and LROAFM phases coexist in the latter three materials. Whether disorder is essential to the generation of spin glass in a strongly frustrated magnet remains to be established. Structurally, $\text{Ca}_3\text{CoNb}_2\text{O}_9$ is a site ordered system which has been confirmed by neutron diffraction experiment¹⁷. However, we can not exclude the possibility of mixing tiny amounts of $\text{Nb}^{5+}/\text{Co}^{2+}$ on the perovskite B -sites. It has been expected that spin glass can be stabilized in geometrically frustrated antiferromagnets even with smallest degree of disorder³¹. After all, based on our current dc susceptibility data, we cannot exclusively determine the origin of observed deviation between the ZFC and FC susceptibility. Specific heat and ac susceptibility experiments down to ^3He temperatures may help to resolve this issue.

To investigate the evolution of magnetism with external field in $\text{Ca}_3\text{CoNb}_2\text{O}_9$, the dc magnetization was measured at 0.46 K [Fig. 5]. The magnetization increases linearly with field and then changes slope around 6 T, which corresponds to a crossover from a long-range ordered state to a fully polarized state, as in $\text{Ba}_3\text{CoNb}_2\text{O}_9$ ^{14,32}. Above 6 T, though the magnetization still increases, it has a tendency to saturate around $2 \mu_B/\text{Co}^{2+}$. Due to spin-orbital couplings and the crystal field, the ground state of Co^{2+} ion coordinated in octahedral environment is a Kramers doublet with an effective spin of $1/2$ ^{33,34}. The low spin state of Co^{2+} has also been observed in many other TLA FM with octahedral Co sites, such as $\text{Ba}_3\text{CoNb}_2\text{O}_9$ ¹⁴, $\text{Ba}_3\text{CoSb}_2\text{O}_9$ ¹² and CsCoCl_3 ². We further plot the first derivative of the magnetization curve as a function of field. Below 6 T, two valleys are observed in the derivative curve, which is reproducible on different samples. The first one is located

FIG. 5: (color online) The magnetization curve of $\text{Ca}_3\text{CoNb}_2\text{O}_9$ at a fixed temperature 0.46 K. The solid squares are M-H curve and the empty ones are the first deviation of magnetization curve as a function of field. The vertical arrows indicate the positions of the valleys.

around 0.7 T, which is consistent with the field where the bifurcation between ZFC and FC susceptibility disappears [Fig. 4 (b)-(f)]. The second one occurs at around 2.5 T with the magnetization of $0.75 \mu_B/\text{Co}^{2+}$, which is close to a $1/3$ of the saturation magnetization (M_s). The possible appearance of a $1/3$ magnetization plateau is consistent with the fact of strong quantum fluctuations from frustration and small effective spins in this triangular lattice^{7,8}. However, we are aware that the magnetization plateau is not strong, which may be because our samples are randomly aligned powders. Single crystal samples are needed to confirm this observation.

Our study revealed that the ground state for $\text{Ca}_3\text{CoNb}_2\text{O}_9$ is a LROAFM coexisting with spin canting or spin glassiness. However, for a regular triangular lattice model, the ground state is coplanar 120° antiferromagnetic order, which has been confirmed in $\text{Ba}_3\text{CoSb}_2\text{O}_9$ ¹², $\text{Ba}_3\text{NiNb}_2\text{O}_9$ ¹³ and $\text{Ba}_3\text{CoNb}_2\text{O}_9$ ¹⁴. The different ground state of $\text{Ca}_3\text{CoNb}_2\text{O}_9$ may be a result of the interplay of strong frustration and anisotropic interactions, and provides possibility of searching for new novel quantum states in this geometrically frustrated magnet. Moreover, the $1/3$ plateau in magnetization for a DTLAF is a macroscopic manifestation of quantum effect predicted by theoretical studies¹¹. To be more unique, this novel magnetic state can be stabilized by a very small field (2.5 T) which is easily accessible by experiments, and provides a promising material for further investigation of magnetization plateaus which

are very interesting theoretically.

IV. CONCLUSION

In conclusion, the magnetism of distorted triangular lattice antiferromagnet $\text{Ca}_3\text{CoNb}_2\text{O}_9$ has been studied for the first time. The large Weiss constant and very low ordering temperature imply strong geometrical frustration in $\text{Ca}_3\text{CoNb}_2\text{O}_9$. Slightly below T_N , a deviation between susceptibility data after ZFC and FC is observed below 0.7 T, which may be related to DM interactions and/or site disorder. A magnetic state with $1/3$ of M_s is suggested in magnetization curve, which may be caused by strong quantum fluctuations in this triangular lattice. $\text{Ca}_3\text{CoNb}_2\text{O}_9$ supplies a new system to study the magnetism of triangular lattice antiferromagnet with weak spatially anisotropic interactions and DM interactions.
